Abstract

Today, most methods for image understanding tasks rely on feed-forward neural networks. While this approach has allowed for empirical accuracy, efficiency, and task adaptation via fine-tuning, it also comes with fundamental disadvantages. Existing networks often struggle to generalize across different datasets, even on the same task. By design, these networks ultimately reason about high-dimensional scene features, which are challenging to analyze. This is true especially when attempting to predict 3D information based on 2D images. We propose to recast 3D multi-object tracking from RGB cameras as an Inverse Rendering (IR) problem, by optimizing via a differentiable rendering pipeline over the latent space of pre-trained 3D object representations and retrieve the latents that best represent object instances in a given input image. To this end, we optimize an image loss over generative latent spaces that inherently disentangle shape and appearance properties. We investigate not only an alternate take on tracking but our method also enables examining the generated objects, reasoning about failure situations, and resolving ambiguous cases. We validate the generalization and scaling capabilities of our method by learning the generative prior exclusively from synthetic data and assessing camera-based 3D tracking on the nuScenes and Waymo datasets. Both these datasets are completely unseen to our method and do not require fine-tuning. Videos and code are available here\textsuperscript{1}.

1. Introduction

The most successful image understanding methods today employ feed-forward neural networks for performing vision tasks, including segmentation [1–3], object detection [4–10], object tracking [11–17] and pose estimation [18, 19]. Typically, these approaches learn network weights using large labeled datasets. At inference time, the trained network layers sequentially process a given 2D image to make a prediction. Despite being a successful approach across disciplines, from robotics to health, and effective in operating at real-time rates, this approach also comes with several limitations: (i) Networks trained on data captured with a specific camera/geography generalize poorly, (ii) they typically rely on high-dimensional internal feature representations which are often not interpretable, making it hard to identify and reason about failure cases, and, (iii) it is challenging to enforce 3D geometrical constraints and priors during inference.

We focus on multi-object tracking as a task that must tackle all these challenges. Accurate multi-object tracking is essential for safe robotic planning. While approaches using LiDAR point clouds (and camera image input) are successful as a result of the explicitly measured depth [12, 15, 17, 20–23], camera-based approaches to 3D multi-object tracking have only been studied recently [13, 14, 24–31]. Monocular tracking methods, typically consisting of independent detection, 3D dynamic models, and matching modules, often struggle as the errors in the distinct modules tend to accumulate. Moreover, wrong poses in the detections can lead to ID switches in the matching process.

We propose an alternative approach that recasts visual inference problems as inverse rendering (IR) tasks, jointly solving them at test time by optimizing over the latent space of a generative object representation. Specifically, we combine object retrieval through the inversion of a rendering pipeline and a learned object model with a 3D object tracking pipeline. This approach allows us to simultaneously reason about an object’s 3D shape, appearance, and three-dimensional trajectory from monocular image input only. The location, pose, shape, and appearance parameters corresponding to the anchor objects are then iteratively refined via test-time optimization to minimize the distance between their corresponding generated objects and the given input image. Rather than directly predicting scene and object attributes, we optimize over a latent object representation to synthesize image regions that best explain the observed image. We match the inverse-rendered objects then be matched by comparing their optimized latents.

Our method hinges on an efficient rendering pipeline and generative object representation at its core. While

\textsuperscript{*}Indicates equal contribution.

\textsuperscript{1}https://light.princeton.edu/inverse-rendering-tracking/
the approach is not tied to a specific object representation, we adopt GET3D [32] as the generative object prior, that is only trained on synthetic data to synthesize textured meshes and corresponding images with an efficient differentiable rendering pipeline. Note that popular implicit shape/object representations do either not support class-specific priors [33, 34], or require expensive volume sampling [35].

The proposed method builds on the inductive geometry priors embedded in our rendering forward model, solving different several tasks simultaneously. Our method refines object pose as a byproduct, merely by learning to represent objects of a given class. Recovering object attributes as a result of inverse rendering also provides interpretability “for free”: once our proposed method detects an object at test time, it can extract the parameters of the corresponding representation alongside the rendered input view. This ability allows for reasoning about failure cases.

We validate that the method naturally exploits 3D geometry priors and generalizes across unseen domains and unseen datasets. After training solely on simulated data, we test on nuScenes [36] and Waymo [37] datasets, and although untrained, we find that our method outperforms both existing dataset-agnostic multi-object tracking approaches and dataset-specific learned approaches [13] when operating on the same detection inputs. In summary, we make the following contributions.

• We introduce an inverse rendering method for 3D-grounded monocular multi-object tracking. Instead of formulating tracking as a feed-forward prediction problem, we propose to solve an inverse image fitting problem optimizing over the latent embedding space of generative scene representations.
• We analyze the single-shot capabilities and the interpretability of our method using the generated image produced by our method during test-time optimization.
• Trained only on synthetic data, we validate the generalization capabilities of our method by evaluating on unseen automotive datasets, where the method compares favorably to existing methods when provided the same detection inputs.

Scope and Limitations While facilitating inverse rendering, the iterative optimization in our method makes it slower than classical object-tracking methods based on feed-forward networks. We hope to address this limitation in the future by accelerating the forward and backward passes with adaptive level-of-detail rendering techniques.

2. Related Work

Object Tracking is a challenging visual inference task that requires the detection and association of multiple objects. Specific challenges include highly dynamic scenes with partial or full occlusions, changes in appearance, and varying illumination conditions [38–40]. In this section, we first review classical tracking methods and deep detection and association methods. Following, we review 3D scene representations and inverse rendering.

3D Object Tracking. An extensively investigated line of work proposes tracking by detection, i.e., to solve the task by first detecting scene objects and then learning to find the associations between the detected objects over multiple frames [41–47]. In addition to association, 3D tracking requires the estimation of object pose. Since directly predicting 3D object pose is challenging [48], most existing 3D tracking methods rely on some explicit depth measurements in the form of Lidar point clouds [15, 49, 50], hybrid camera-lidar measurements [48] or stereo information [28, 51]. Weng et al. [16] proposed a generic tracking method that combines a 3D Kalman filter and the Hungarian algorithm for matching on an arbitrary object detector.

Only recent work [13, 14, 24–26] tackles monocular 3D tracking. Hu et al. [24] relies on similarity across different viewpoints to learn rich features for tracking. DEFT [14] jointly trains the feature extractor for detection and tracking using the features to match objects between frames. In contrast, Marinello et al. [26] use an off-the-shelf tracker and enhance image features with 3D motion and bounding box information. Zhou et al. [13] rely on a minimal input of two frames and predicted heatmaps to perform simultaneous detection and tracking. Some 3D tracking methods rely on motion models [52–54] such as the Kalman Filter [55]. Recent methods also make use of optical flow predictions [56], learned motion models metrics [29], long short-term memory modules (LSTM) [14, 24, 26] and more recently transformer modules [30, 31]. All the above methods rely on a feed-forward image encoder backbone to predict object features. Departing from this approach, we propose a multi-object tracking method that directly optimizes a consistent three-dimensional reconstruction of objects and 3D motion via an inverted graphics pipeline.

3D Scene Representations, Generation and Neural Rendering. A growing body of work addresses joint 3D reconstruction and detection from monocular cameras. Existing methods have exploited different geometrical priors [57] for this task, including meshes [58], points [59], wire frames [60], voxels [61] CAD models or implicit functions [62] signed distance functions (SDFs) [63]. Early approaches in neural rendering represent the scene explicitly by, e.g., encoding texture or radiance on the estimated scene geometry [64] or using volumetric pixels (Voxels) [65]. Other methods represent 3D scenes implicitly. This includes the successful NeRF method [34] and variants that have been extended to dynamic scenes [62, 66, 67]. To al-
Inverse Rendering methods conceptually “invert” the graphics rendering pipeline, which generates images from 3D scene descriptions, and instead estimates the 3D scene properties, i.e., geometry, lighting, depth, and object poses based on input images. Recent work [77–79] successfully achieved joint optimization of a volumetric model and unknown camera poses from a set of images merely by back-propagating through a rendering pipeline. Another area of inverse rendering focuses on material and lighting properties [80–82], to find a representation that best models the observed image.

To the best of our knowledge, we present the first method that employs an inverse rendering approach for multi-object 3D tracking, without any feed-forward prediction of object features – only given 2D image input.

3. Tracking by Inverse Rendering

We cast object tracking as a test-time inverse rendering problem that fits generated multi-object scenes to the observed image frames. First, we discuss the proposed scene representation we fit. Next, we devise our rendering-based test-time optimization at the heart of the proposed tracking approach. The full tracking pipeline is illustrated in Fig. 1. We employ an object-centric scene representation. We model the underlying 3D scene for a frame observation as a composition of all object instances without the background scene.

3.1. Scene Generation

**Object Prior.** To represent a large, diverse set of instances per class, we define each object instance \( o \) as a sample from a distribution \( O \) over all objects in a class, that is

\[
O \sim f(o),
\]

where \( f \) is a learned function over a known prior object distribution. Here, the prior distribution is modeled by a differentiable generative 3D object model \( o_p = G(z_p), \) that maps a latent embedding \( z_p \) to an object instance \( o_p \), the object \( p \). In particular, the latent space comprises two disentangled spaces \( z_S \) and \( z_T \) for shape \( S \) and texture \( T \). 

**Inverse Rendering.** Inverse rendering methods conceptually “invert” the graphics rendering pipeline, which generates images from 3D scene descriptions, and instead estimates the 3D scene properties, i.e., geometry, lighting, depth, and object poses based on input images. Recent work [77–79] successfully achieved joint optimization of a volumetric model and unknown camera poses from a set of images merely by back-propagating through a rendering pipeline. Another area of inverse rendering focuses on material and lighting properties [80–82], to find a representation that best models the observed image.
Given an object-centric camera projection $P_c = K_c T$, where $K_c$ is the camera intrinsic matrix, a transformation $T = [R | t]$ to camera $c$ that is composed of rotation $R$ and translation $t$, a differentiable rendering method $R(o_p, c)$, such as rasterization for meshes or volumetric rendering for neural fields, this renders an image $I_{c,p}$, a 2D observation of the 3D object $o_p$. While our method is general, implementation details of the generator and rendering method are provided in the implementation section.

Scene Composition. We model a multi-object scene as a scene graph composed of transformations in the edges and object instances in the leaf nodes, similar to Ost et al. [62]. Object poses are described by the homogeneous transformation matrix $T_p \in \mathbb{R}^{4 \times 4}$ with the translation $t_p$ and orientation $R_p$ in the reference coordinate system. The camera pose $T_c \in \mathbb{R}^{4 \times 4}$ is described in the same reference coordinate system. The relative transformation of the camera $c$ and each object instance $p$ can be computed through edge traversal in the scene graph as

$$T_{c,p} = \text{diag} \left( \frac{1}{s_p} \right) T_p T_c^{-1}, \quad (2)$$

where the factor $s_p$ is a scaling factor along all axes to allow a shared object representation of a unified scale. This canonical object scale is necessary to represent objects of various sizes, independent of the learned prior on shape and texture. The object centric projection $P_{c,p} = K_c T_{c,p}$ is used to render the RGB image $I_{c,p} \in \mathbb{R}^{H \times W \times 3}$ and mask $M_{c,p} \in [0, 1]^{H \times W}$ for each object/camera pair.

Individual rendered RGB images are ordered by object distance $\|t_{c,p}\|$, such that $p = 1$ is the shortest distance to $c$. Using the Hadamard product of the non-occluded mask $\gamma_p$ all $N_o$ object images are composed into a single image

$$\hat{I}_c = \sum_{k=1}^{N_o} R(G(z_{S,p}, z_{T,p}), P_{c,p}) \circ \gamma_p, \quad \text{where}$$

$$\gamma_p = \max \left( \left( M_{c,p} - \sum_{q=1}^{p} M_{c,q} \right), 0 \right)^{H \times W}, \quad (3)$$

where instance masks are generated in the same fashion.

3.2. Inverse Multi-Object Scene Rendering.

We invert the differentiable rendering model defined in Eq. 3 by optimizing the set of all object representations in a given image $I_c$ with gradient-based optimization. We assume that, initially, each object $o_p$ is placed at a pose $T_{c,p}$ and scaled with $s_p$, near its underlying location. We represent object orientations in their respective Lie algebraic form $so(3)$. We further sample an object embedding $z_{S,p}$ and $z_{T,p}$ in the respective latent embedding space.

For in-the-wild images, $I_c$ is not just composed of sampled object instances but other objects and the scene background. Since our goal for tracking is the reconstruction of all object instances of specific object classes, a naive $\ell_2$ image matching objective of the form $\|I_c - \hat{I}_c\|_2$ is noisy and challenging to solve with vanilla stochastic gradient descent methods. To tackle this issue, we optimize visual similarity in the generated object regions instead of the full image. We optimize only on rendered RGB pixels and minimize

$$\mathcal{L}_{RGB} = \| (I_c - \hat{I}_c) \circ \hat{M}_c \|_2,$$

with $\hat{M}_c = \min \left( \sum M_{c,p}, 1 \right). \quad (4)$

The mask of all foreground/object pixels $\hat{M}_c$ is computed as the sum over all object masks $M_{c,p}$ in the frame rendered by camera $c$. We employ a learned perceptual similarity metric [83] (LPIPS) on object-centered image patches, that is

$$\mathcal{L}_{perceptual} = \text{LPIPS}_{\text{patch}} (I_c; \hat{I}_{c,p}). \quad (5)$$

The combined loss function of our method is

$$\mathcal{L}_{IR} = \mathcal{L}_{RGB} + \lambda \mathcal{L}_{perceptual}, \quad (6)$$

which we optimize by refining the latent codes of shape and appearance, position, rotation, and scale, leading to

$$z_{S,p}, z_{T,p}, \hat{s}_p t_p, R_p = \arg \min \left( \mathcal{L}_{IR} \right). \quad (7)$$

Instead of using vanilla stochastic gradient descent methods, we propose an alternating optimization schedule of distinct properties that includes aligning $z_S$ before $z_T$, to reduce the number of total optimization steps. A detailed implementation and validation of all design choices of the optimization are presented in the Supplementary Material.

Optimization. To solve Eq. 6, we propose an optimization schedule, that first optimizes a coarse color, and then jointly optimizes the shape and the positional state of each object. As the backbone of the learned perceptual loss, we use a pre-trained VGG16 [84] and utilize individual output feature map similarities at different points of the optimization. We find that color and other low-dimensional features are represented in the initial feature maps and those are better guidance for texture than high-dimensional features as outputs of the later blocks. These features have a more informative signal for shape and object pose. We use the average of the first and second blocks in the optimization for $z_T$, while the combined perceptual similarity loss guides the optimization of $z_T$ and the pose.

We initialize all object embeddings with the same fixed values inside the embedding space, take two optimization steps solely on color utilizing the described loss, and then
3.3. 3D MOT via Inverse Rendering

Next, we describe the proposed method for tracking multiple dynamic objects with the inverse rendering approach from above. The approach tracks objects in the proposed representation across video frames and is illustrated in Fig. 1. For readability, we omit \( p \) and the split of \( z \) into \( z_S \) and \( z_T \) in the following.

### Initial Object and Pose Estimation.

Common to tracking methods, we initialize with a given initial 3D detection on image \( I_{t_k} \), and we set object location \( t_k = [x, y, z]_k \), scale \( s_k = \max(w_k, h_k, l_k) \) using the detected bounding box dimensions and heading \( \psi_k \) in frame \( k \). We then find an optimal representation \( z_o \), and a refined location and rotation of each object \( o \) via the previously introduced inverse rendering pipeline for multi-object scenes. The resulting location, rotation, and scale lead to the observation vector

\[
y_k = [t_k, s_k, \psi_k].
\]  

### Prediction.

While not confined to a specific dynamics model, we use a linear state-transition model \( A \), for the objects state \( x_k = [x, y, z, \psi, w, l, x', y', z']_k \), and a forward prediction using a Kalman Filter \([55]\), a vanilla approach in 3D object tracking \([16]\). An instantiated object in \( k-1 \) can be predicted in frame \( k \) as

\[
\begin{align*}
\hat{x}_{k|k-1} &= Ax_{k-1|k-1} \\
\text{and } P_{k|k-1} &= AP_{k-1|k-1}A^T + Q,
\end{align*}
\]  

with the predicted \textit{a priori} covariance matrix modeling the uncertainty in the predicted state.

### Interpretable Latent Matching.

In the matching stage, all optimal object representations \( o_p \) in frame \( k \) are matched with \textit{tracked} and \textit{lost} objects from \( k - 1 \). Objects are matched based on appearance and location with a weighted affinity score

\[
A = w_{IoU}A_{IoU,3D} + w_zA_z + w_cD_{centroid},
\]  

where \( A_{IoU,3D} \) is the IoU of the 3D boxes computed over the predictions of tracked object predictions \( x_{k|k-1} \) and refined observations. Here, the object affinity \( A_z \) is computed as the cosine distance of tracked object latent embeddings \( z \).
In addition to that the Euclidean distance between the center $D_{center}$ adds additional guidance. We add no score for unreasonable distant tracked objects and detections.

We compute the best combination of tracked and detected objects using the Hungarian algorithm [86], again a conventional choice in existing tracking algorithms. Matched tracklet and object pairs are kept in the set of tracked objects and the representation of the corresponding detections is discarded, while unmatched detections are added as new objects. Unmatched tracklets are set to lost with a lost frame counter of one. Objects that were not detected in previous frames are set to tracked and their counter is reset to 0. Objects with a lost frame count higher than $N_{T_{life}}$ are removed.

**Track and Embedding Update.** In the update step, we refine each object embedding $z$ and motion model $y_k$ given the result of the matching step. Embeddings are updated through an exponential moving average

$$z_{k,EMA} = \beta z_k + (1-\beta)z_{k-1,EMA} \quad \text{with} \quad \beta = \frac{2}{T+1} \quad (12)$$

over all past observations of the object, where $T$ is the number of observed time steps of the respective instance. The observation $y_k$ is used to update the Kalman filter. The optimal Kalman gain

$$K_k = P_{k|k-1} H^T (HP_{k|k-1} H^T + R)^{-1} \quad (13)$$

is updated to minimize the residual error of the predicted model and the observation. The observation $y_k$ is used to estimate the object state as

$$\hat{x}_{k|k} = \hat{x}_{k|k-1} + K_k(y_k - H\hat{x}_{k|k-1}) \quad (14)$$

and with

$$P_k = P_{k|k-1} - K_k H P_{k|k-1} \quad (15)$$

the *a posteriori* of the covariance matrix is updated.

### 3.4. Implementation Details

**Representation Model.** We employ the GET3D [32] architecture as object model $G$. Following StyleGAN [72, 73] embeddings $z_T$ and $z_S$ are mapped to intermediate style embeddings $w_S$ and $w_T$ in a learned $W$-space, which we optimize over instead of $Z$-space. Style embeddings condition a generator function that produces tri-planes representing object shapes as Signed Distance Fields (SDFs) and textures as texture fields. We deliberately train our generator on synthetic data only, see experiments below. Differentiable marching tetrahedra previously introduced in DMTeT [88] extract a mesh representation and Images are rendered with a differentiable rasterizer [89].

**Computational Cost.** Each IR optimization step in our implementation takes $\sim 0.3$ seconds per frame. The generation and gradient computation through the generator determines the computational cost of the method. However, we note that the rendering pipeline, contributing the majority of the computational cost of the generator, has not been performance-optimized and can be naively parallelized when implemented in lower-level GL+CUDA graphics primitives.

### 4. Experiments

In the following, we assess the proposed method. Having trained our generative scene model solely on simulated data [90], we test the generalization capabilities on the nuScenes [36] and Waymo [37] dataset – both are unseen by the method. We analyze generative outputs of the test-time optimization and compare them against existing 3D multi-object trackers [13, 16, 24, 29, 31] on camera-only data.
Table 1. Quantitative Evaluation for Camera-only Multi-Object Tracking. Quantitative results on “cars” in the test split of the nuScenes tracking dataset [36]. Our IR-based tracker outperforms AB3DMOT [16] on all metrics and CenterTrack [13] on accuracy. All three methods use the same detection backbone for fair comparison, while only CenterTrack requires end-to-end training on the dataset. Additional results show on-par performance of our method with QD-3DT [24] trained on nuScenes [36]. QD-3DT trained on the Waymo Open Dataset (WOD) does not generalize to nuScenes and does not achieve competitive results. Only very recent transformer-based methods, such as PF-Track [30] and the metric learning approach of Q-Track [29] achieve a higher score. However, these methods require end-to-end training on each dataset. “CP” denotes here the vision-only version of CenterPoint [87] was used for object detection. Bold denotes best and underlined second best for methods that did not train on the dataset or use the same detection backbone.

4.1. Single-Shot Object Retrieval and Matching

Although trained only on general object-centric synthetic data, ShapeNet [90], our method is capable of fitting a sample from the generative prior to observed objects in real datasets that match the vehicle type, color, and overall appearance closely, effectively making our method dataset-agnostic. We analyze the generations during optimization in the following.

Optimization. Given an image observation and coarse detections, our method aims to find the best 3D representation, including pose and appearance, solely through inverse rendering. In Fig. 4 we analyze this iterative optimization process, following a scheduled optimization as described in Sec. 3.4. We observe that the object’s color is inferred in only two steps. Further, we can observe that even though the initial pose is incorrect, rotation and translation are optimized jointly through inverse rendering together with the shape and scale of the objects, recovering from sub-optimal initial guesses. The shape representation close to the observed object is reconstructed in just 5 steps.

4.2. Evaluation

To provide a fair comparison of 3D multi-object tracking methods using monocular inputs, we compare against existing methods by running all our evaluations with the method reference code. We only evaluate methods, that consider past frames, but have no knowledge about future frames, which is a different task. While our method does not store the full history length of all images, we allow such memory techniques for other methods. We only consider purely mono-camera-based tracking methods. We note that, in contrast to our method, most baseline methods we compare to are finetuned on the respective training set. For all two-stage detect-and-track methods, we use CenterPoint [15] as the detection method. We compare to CenterTrack [13] as an established learning-based baseline, and present results of the very recent PFTrack [30], a transformer-based tracking method, Qtrack [29] as a metric learning method, and QD-3DT [24] as an LSTM-based state tracker combined with image feature matching. Of all learning-based methods, only CenterTrack [13] allows us to evaluate tracking performance with identical detections. Finally, we compare to AB3DMOT [16] that builds on an arbitrary 3D detection algorithm and combines it with a modified Kalman filter to track the state of each object. AB3DMOT [16] and the proposed method are the only methods that are data-agnostic in the sense that they have not seen the training dataset. For a fair evaluation of these generalization capabilities in learning-based methods, we include another version of QD-3DT solely trained on the Waymo Open Dataset [37] and evaluate on nuScenes [36]. We discuss the findings in the following.

Validation on nuScenes. Tab. 1 reports quantitative results on the test split of the nuScenes tracking dataset [36] on the car object class for all six cameras. We list results for the multi-object tracking accuracy (MOTA) [91] metric, the AMOTA [16] metric, average multi-object tracking precision (AMOTP) [16] and recall of all methods. First, we evaluate a version of QD-3DT [24] that has been trained on the Waymo Open Dataset [37] (WOD) but tested on nuScenes. This experiment is reported in row four of Tab. 1 and confirms that recent end-to-end detection and tracking methods do not perform well on unseen data (see qualitative results in the Supplementary Material). Moreover, perhaps surprisingly, even when using use the same vision-only detection backbone as in our approach, the established end-to-end trained baseline CenterTrack [13], which has seen
the dataset, performs worse than our method. Our IR-based method outperforms the general tracker AB3DMOT [16]. When other methods are given access to the dataset, recent learning-based methods such as the end-to-end LSTM-based method QD-3DT [24] perform on par. Only the most recent transformer-based methods such as PF-Track [30] and the QTrack [29], which employ a quality-based association model on a large set of learned metrics, such as heat maps and depth, achieve higher scores. Note again, that these methods, in contrast to the proposed method, have been trained on this dataset and cannot be evaluated independently of their detector performance.

We visualize the rendered objects predicted by our tracking method in Fig. 2. We show an observed image from a single camera at time step $k = 0$, followed by rendered objects overlaid over the observed image at time step $k = 0, 1, 2$ and 3 along with their respective bounding boxes, with color-coded tracklets. We see that our method does not lose any tracks in challenging scenarios in diverse scenes shown here, from dense urban areas to suburban traffic crossings, and handles occlusions and clutter effectively. By visualizing the rendered objects as well as analyzing the loss values, our method allows us to reason about and explain success and failure cases effectively, enabling explainable 3D object tracking. The rendered output images provide interpretable inference results that explain successful or failed matching due to shadows, appearance, shape, or pose. For example, the blue car in the IR inference in Fig. 5 top row was incorrectly matched due to an appearance mismatch in a shadow region. A rendering model including ambient illumination may resolve this ambiguity; see further discussion in the Supplementary Material.

**Interpretation.** Fig 5 shows the inverse rendered scene graphs in isolation and birds-eye-view tracking outputs on a layout level. Our method accurately recovers the object pose, instance type, appearance, and scale. As such, our approach directly outputs a 3D model of the full scene, i.e., layout and object instances, along with the temporal history of the scene recovered through tracking – a rich scene representation that can be directly ingested by downstream planning and control tasks, or simulation methods to train downstream tasks. As such, the method also allows us to reason about the scene by leveraging the 3D information provided by our predicted 3D representations. The 3D locations, object orientations, and sizes recovered from such visualizations can not only enable us to explain the predictions of our object tracking method, especially in the presence of occlusions or ID switches but also be used in other downstream tasks that require rich 3D understanding, such as planning.

**Validation on Waymo.** Next, we provide qualitative results from the 3D tracking on the validation set of WOD [37] in Fig. 3. The only public results on the provided test set are presented in QD-3DT [24], which may indicate it fails on this dataset. While the size of the dataset and its variety is of high interest for all autonomous driving tasks, Hu et al. [24] conclude that vision-only test set evaluation is not representative of a test set developed for surround view lidar data on partial unobserved camera images only. As such, we provide here qualitative results in Fig. 3, which validate
Table 2. Ablation Experiments.

(a) Input Frame (b) Full (ours) (c) No Schedule

Input frame is faded for visibility.

(a) Effect of Optimization Schedule. (a) observed image, (b) optimized generations using the proposed schedule in Sec. 3. (c) optimized generations using no schedule. This supports the quantitative to the left.

(b) Optimization Schedule and Loss Components. Ablations were run on a small subset of the nuScenes [36] validation set. $L_{RGB}$ fails due to the optimizer fitting objects to the background instead, increasing the size of each object resulting in out of memory.

that the method achieves tracking of similar quality on all datasets, providing a generalizing tracking approach. We show that our method does not lose tracks on Waymo scenes in diverse conditions.

4.3. Ablation Experiments

As ablation experiments, we analyze the optimization schedule, the INR loss function components, and the weights of the tracker, applying them to a subset of scenes from the nuScenes validation set. We deliberately select this smaller validation set due to its increased difficulty. The top row of Tab. 2b lists the quantitative results from our ablation study of the optimization schedule. Our findings reveal a crucial insight: the strength of our method lies not in isolated loss components but in their synergistic integration. Specifically, the amalgamation of pixel-wise, perceptual, and embedding terms significantly enhances AMOTA, MOTA, and Recall metrics.

Moreover, the absence of an optimization schedule led to less robust matching as quantitative and qualitative results in Tab. 2a reveal. However, the core efficacy of our tracking method remained intact as indicated in the last row of Tab. 2b. This nuanced understanding underscores the importance of component interplay in our method.

5. Conclusion

We investigate inverse neural rendering as an alternative to existing feed-forward tracking methods. Specifically, we recast 3D multi-object tracking from RGB cameras as an inverse test-time optimization problem over the latent space of pre-trained 3D object representations that, when rendered, best represent object instances in a given input image. We optimize an image loss over generative latent spaces that inherently disentangle shape and appearance properties. This approach to tracking also enables examining the reconstructed objects, reasoning about failure situations, and resolving ambiguous cases – rendering object layouts and loss function values provides interpretability “for free”. We validate that the method has high generalization capabilities, and without seeing a dataset, outperforms existing tracking methods’ generalization capabilities. In the future, we hope to investigate not only object detection with inverse rendering but broad, in-the-wild object class identification via conditional generation methods – unlocking analysis-by-synthesis in vision with generative neural rendering.
